

Dilute proparacaine for the management of acute corneal injuries in the emergency department

Ian Michael Ball, MD;^{*} Jamie Seabrook, MA;[†] Nimesh Desai, BSc(Pharm), MD;[‡] Larry Allen, MD;[‡] Scott Anderson, MD^{*}

ABSTRACT

Objective: Dogma discourages the provision of topical anesthetics to patients with corneal injuries discharged from the emergency department because of the toxicity of concentrated solutions. We compared the analgesic efficacy of dilute topical proparacaine with placebo in emergency department patients with acute corneal injuries.

Methods: We conducted a prospective randomized controlled trial of adults with corneal injuries presenting to one of 2 tertiary care emergency departments in London, Ont. Patients were randomly assigned to groups receiving either 0.05% proparacaine or placebo drops as outpatients and were followed up to healing by a single ophthalmologist. Our primary outcome was pain reduction as measured on a 10-cm visual analog scale.

Results: Fifteen participants from the proparacaine group and 18 participants from the placebo group completed the study. The mean age of the patients was 38.7 (standard deviation 12.3) years and the majority were male (85%). Pain reduction was significantly better in the proparacaine group than in the placebo group, with a median improvement of 3.9 (interquartile range [IQR] 1.5–5.1) cm on the visual analog scale versus a median improvement of 0.6 (IQR 0.2–2.0) cm ($p = 0.007$). The proparacaine group was more satisfied (median level of satisfaction 8.0 [IQR 6.0–9.0] cm on a 10-cm visual analog scale v. 2.6 [IQR 1.0–8.0] cm, $p = 0.027$). There were no ocular complications or signs of delayed wound healing in either group.

Conclusion: Dilute topical proparacaine is an efficacious analgesic for acute corneal injuries. Although no adverse events were observed in our study population, larger studies are required to evaluate safety.

Keywords: proparacaine, pain, cornea, abrasion

RÉSUMÉ

Objectif : Le dogme déconseille aux médecins de remettre aux patients présentant des lésions cornéennes des anesthésiques topiques à leur sortie de l'urgence, en raison de la

toxicité des solutions concentrées. Nous avons comparé l'efficacité analgésique de la proparacaine diluée appliquée localement à celle d'un placebo chez des patients s'étant présentés à l'urgence avec des lésions cornéennes aiguës.

Méthodes : Nous avons réalisé un essai contrôlé randomisé prospectif auprès d'adultes ayant des lésions cornéennes et s'étant présentés à l'un des deux services d'urgence d'un centre hospitalier de soins tertiaires à London, en Ontario. Les patients ont été répartis au hasard entre des groupes recevant dans une clinique externe soit de la proparacaine à 0,05 %, soit des gouttes d'un placebo. Ils ont été suivis jusqu'à la guérison par un seul ophtalmologiste. Notre principal critère d'évaluation était la réduction de la douleur, mesurée sur une échelle visuelle analogique (EVA) de 0 à 10 cm.

Résultats : Quinze participants du groupe proparacaine et 18 du groupe placebo ont terminé l'étude. L'âge moyen des patients était de 38,7 ans (écart-type de 12,3) et la majorité était de sexe masculin (85 %). La réduction de la douleur était significativement meilleure dans le groupe proparacaine que dans le groupe placebo, avec une amélioration médiane de 3,9 cm (intervalle interquartile [IIQ] de 1,5 à 5,1) sur l'EVA par rapport à une amélioration médiane de 0,6 cm (IIQ de 0,2 à 2,0, $p = 0,007$). Le groupe proparacaine était plus satisfait des résultats (niveau de satisfaction médian de 8,0 cm [IIQ de 6,0 à 9,0]) sur l'EVA contre 2,6 cm [IIQ de 1,0 à 8,0], $p = 0,027$). Aucune complication oculaire ou aucun signe de retard de cicatrisation n'ont été notés dans les deux groupes.

Conclusion : La proparacaine diluée appliquée localement est un analgésique efficace pour les lésions cornéennes aiguës. Bien qu'aucun effet indésirable n'ait été observé dans cette population d'étude, des études de plus grande envergure s'imposent pour évaluer l'innocuité.

INTRODUCTION

Acute corneal injuries are a common complaint in the emergency department. They cause significant patient

morbidity, including pain, loss of sleep and missed work. The approach to pain management varies in this patient population and includes the following: no analgesia, oral or topical nonsteroidal anti-inflammatory drugs (NSAIDs), oral opiates and cycloplegics.¹ Topical agents can reduce pain; however, their use must be limited. Topical NSAIDs have induced sterile corneal infiltrates.² Textbooks state that prolonged topical application of local anesthetics is contraindicated^{3,4} because of their inhibition of mitosis and cellular migration.⁵ Local anesthetics are said to impair the ability of the corneal epithelium to oxidize glucose and pyruvate.⁵ Topical anesthetics can markedly decrease corneal sensation to touch, which is an important corneal protective mechanism.⁶ At commonly encountered concentrations (e.g., 0.5% proparacaine), these agents are also directly toxic to the cornea with prolonged and repeated use,^{5,7-9} causing increased corneal thickness, opacification, stromal infiltration and punctate epithelial defects.¹⁰⁻¹²

Several publications in the ophthalmology literature have reported that the outpatient use of more dilute topical anesthetics is safe and effective after photorefractive surgery.¹³⁻¹⁵ We asked whether dilute 0.05% proparacaine applied topically would be efficacious in patients with acute corneal injuries discharged from the emergency department. Our primary outcome was pain reduction from baseline as measured on a 10-cm visual analog scale. Secondary end points included patient satisfaction with the study drug, use of medications for breakthrough pain, and signs of delayed wound healing or corneal toxicity on follow-up.

METHODS

Design

We performed a prospective randomized double-blind placebo-controlled trial on adults with corneal injuries.

Setting and study population

Our study was performed at 2 tertiary care emergency departments in London, Ont., with a combined census of approximately 120 000 visits per year. We enrolled a convenience sample of adult patients during an 8-month period beginning in October 2005. Patients were excluded if they had any of the following: inability to consent to the study, allergy to any of the study medications, inability to attend follow-up appointments for any reason, or previous eye injury or pathology.

Interventions

Patients were randomly assigned to groups receiving either 0.05% proparacaine or a colour- and smell-matched placebo. The usual single-dose topical anesthetic used to facilitate eye examination in the participating emergency departments is 0.5% proparacaine. Our pharmacy diluted this usual medication 10-fold, emulating a previous postoperative study.¹⁵ Patients were instructed to use 2 to 4 drops of the study drug on an as-needed basis for the next 7 days. No minimum time interval between dosing was stipulated, allowing patients unlimited use of the study drug. A total volume of 40 mL was dispensed to each patient.

Participants were given a pain log, topical fluoroquinolone and tablets of 325 mg acetaminophen with 30 mg of codeine for breakthrough pain. Patients received an instruction sheet explaining how to use the pain logs as well as an information sheet explaining the goals of the trial. All patients included in the study were prescribed topical gatifloxacin, 1–2 drops every 2 hours to the affected eye while awake for the duration of the study period. They were instructed to take 1 to 2 tablets of the acetaminophen with codeine every 4 hours if needed. Patients were asked to record their use of oral analgesics, and to bring all unused pills to clinic follow-up appointments, where they were counted.

Outcome measures

Participants were asked to complete the visual analog scale¹⁶ describing their pain immediately before, and 5 minutes after self-administration of the study drug. On the 10-cm scale, 0 indicated “no pain” and 10 indicated “the worst imaginable pain.” The pre- and post-drug visual analog scales were printed on the same sheet of paper, allowing the participant to see both scales at the time of scoring. The primary outcome was the mean difference in pain scores before and after drug administration as recorded by each study participant. Satisfaction was recorded by participants using a separate 10-cm visual analog scale (0 = completely unsatisfied, 10 = completely satisfied).

All patients attended for follow-up at an outpatient clinic on days 1, 3 and 5 after enrolment by a single ophthalmologist, who was unaware of the patient allocation. The ophthalmologist was directed to identify signs of delayed wound healing, increased corneal thickness, corneal opacification, new corneal epithelial defects or any other ocular pathology that could be related to

either the initial injury or the use of study medication. Patients made additional visits thereafter at the discretion of the observing ophthalmologist. At the final ophthalmology clinic visit, the pain logs were collected.

Patient recruitment

The attending emergency physician and emergency medicine residents on duty recruited patients into the study. The total number of patients eligible for inclusion in the trial during the 8-month trial period was not recorded. No attempt was made to measure the severity of the corneal injury, either in the emergency department or at follow-up.

Randomization and concealment

Staff at the hospital pharmacy diluted the proparacaine and filled numbered vials with either proparacaine or placebo. These vials were distinguishable only by number. The randomization key was generated via a computer using the random number function of Excel (Microsoft). The lead author and pharmacist were the only 2 people with access to the randomization key. The randomization key was made available to the lead author only after study completion. The contents of the study drug vial were concealed from all personnel involved in patient care, as well as from the patients themselves. Treating physicians were instructed to select the next available vial to dispense to the participant at the time of enrolment. The allocation was confirmed by inspection of the numbered vial at follow-up.

Ethics

Patients provided written consent to the emergency physician at the time of enrolment as approved by our institution's research ethics board.

Statistical analysis

Data were analyzed using SPSS, version 15.0 (SPSS Inc.). Data are reported as means and standard deviations for normally distributed continuous variables, or medians and interquartile ranges (IQRs) for skewed continuous variables. Percentages were used for categorical variables. The Mann–Whitney test was used to compare differences in pain reduction, drug satisfaction and number of oral tablets taken between the groups.

Sample size

We determined that 16 participants in each group would be needed to have an 80% chance of detecting a pain reduction of 2 cm on the visual analog scale between the 2 groups, assuming an α of 0.05, and a standard deviation of 2 cm. We chose 2 cm to represent a clinically meaningful difference based on an informal survey of attending emergency physicians at our hospital.

RESULTS

Fifteen participants from the proparacaine group and 18 participants from the placebo group completed the study. Eight enrolled patients either did not use even a

single dose of medication, did not record their pain in their pain logs or were lost to follow-up. These patients were removed from the trial entirely, and were not included in an intent to treat fashion.

The mean age in the proparacaine group was 38.0 years, and in the placebo group was 39.3 years. In the proparacaine group, 87% of participants were male, and in the placebo group 83% were male. All injuries were caused by trauma that had occurred within 24 hours of presentation to the emergency department.

Table 1 shows patient outcomes between the 2 groups. Pain reduction 5 minutes after administration of the study drug was significantly better in the proparacaine group than in the placebo group (Fig. 1) (median improvement 3.9 [IQR 1.5–5.1] cm on the visual analog scale v. 0.6 [IQR 0.2–2.0] cm, $p = 0.007$). The proparacaine group was also much more satisfied (Fig. 2) (median level of satisfaction 8.0 [IQR 6.0–9.0] cm v. 2.6 [IQR 1.0–8.0] cm, $p = 0.027$). The placebo group took more acetaminophen with codeine tablets (median 2.0 [IQR 0.0–5.0] tablets) than the proparacaine group (median 0.0 [IQR 0.0–2.0] tablets) but this difference was not statistically significant (Fig. 3) ($p = 0.22$).

There was no difference in frequency of administration of the study drug between the 2 groups based on pain logs. There were also no ocular complications or evidence of delayed wound healing in either group.

DISCUSSION

Fig. 1. Reduction in pain 5 minutes after drop application. The Δ between the mean pain score before administration of the study drug, and the mean pain score 5 minutes after administration is shown for each participant. The diamonds represent the mean Δ pain scores for each study participant. The upper and lower borders of each rectangle represent the 75th and 25th percentiles of mean pain reduction. The horizontal line within each rectangle represents the median pain reduction. VAS = visual analog scale.

Many physicians receive requests from patients for a topical anesthetic prescription after the initial dose administered in the emergency department provides complete relief. Dogma instructs us to never prescribe outpatient topical anesthesia for corneal injuries.

The findings of this study were consistent with those of 3 similar studies in the ophthalmology literature. Each study found that brief outpatient use of dilute topical anesthetic was safe and effective as an analgesic.^{13–15} The clinically significant differences in pain reduction and patient satisfaction in our study demonstrate the efficacy of diluted proparacaine.

Fig. 2. The diamonds represent the satisfaction scores for each study participant. The upper and lower borders of each rectangle represent the 75th and 25th percentiles of patient satisfaction. The horizontal line within each rectangle represents the median patient satisfaction. VAS = visual analog scale.

Fig. 3. Rescue doses of oral analgesia. The diamonds represent the mean number of tablets of acetaminophen with codeine used by each patient after each use of the study drug. The upper and lower borders of each rectangle represent the 75th and 25th percentiles of mean number of tablets used per patient. The horizontal line within each rectangle represents the median of the mean number of tablets used per patient.

Although there was a similar time to pain relief in both groups among the patients who achieved pain relief, a small number of patients in the placebo group continued to use rescue oral acetaminophen with codeine tablets for a longer period.

The literature provides examples of corneal toxicity from repeat application of concentrations of anesthetic intended for 1-time dosing,¹⁰⁻¹² generally on the order of 10 times greater than the concentration that we used. Such toxicity has also been described with injected 0.75% bupivacaine, 4% lidocaine, 0.5% proparacaine and 0.5% tetracaine in rabbits.¹⁷ This same rabbit study supports the safety of dilute injected anesthetic agents. An abundance of evidence exists for the toxicity of topical anesthetic when abused.¹⁸⁻²⁴ We did not observe any evidence of harm from dilute-strength topical anesthetic used for a prescribed duration.

Patients in our study were encouraged to use the drops as frequently as needed. Despite the liberal prescription of the study drug, both groups administered most of their drops during the first 24 hours. We speculate that patients in the study drug arm achieved adequate analgesia quickly, and did not require much further analgesic use. Should such patients require analgesia for only 24 to 36 hours, clinicians could prescribe smaller volumes of anesthetic for a shorter duration, which may further improve safety.

The use of prophylactic topical antibiotics in the uncomplicated corneal injury is controversial and not standard practice in our emergency departments. We added topical antibiotics in consultation with ophthalmology colleagues who participated in the study.

Although our study found no evidence of harm from proparacaine, our patients were dispensed a limited volume of dilute anesthetic. Nonetheless, at the end of 5-7 days, all of our patients showed evidence of appropriate injury healing and no patient had continued pain.

Limitations

This study was performed at a single centre and enrolled a small number of patients. It was not powered for important safety outcomes. We had hoped to enrol consecutive patients but suspect that recruiting physicians missed many eligible patients. No attempt was made to measure the severity or the cause of the corneal injury. We did attempt to verify patient compliance with our protocol by counting remaining tablets, but we did not attempt to measure volume of study drug remaining at follow-up.

CONCLUSION

Dilute topical anesthetic is an efficacious analgesic in patients with corneal injuries discharged from the emergency department. Treatment with dilute topical anesthetics may be effective and safe when prescribed for 1 to 2 days. Larger studies powered for safety are necessary before widespread adoption of this practice.

Important Safety Information

EpiPen® and EpiPen® Jr Auto-injectors are indicated for the emergency treatment of anaphylactic reactions in patients who are determined to be at increased risk for anaphylaxis, including individuals with a history of anaphylactic reactions. They are intended for immediate self-administration for the emergency treatment of severe allergic reactions (Type I), including anaphylaxis associated with foods, stinging and biting insects, medications, latex, other allergens, and for idiopathic and exercise-induced anaphylaxis. Selection of the appropriate dosage strength is determined according to patient body weight.

There are no absolute contraindications to the use of epinephrine in a life-threatening allergic situation. Epinephrine use should be avoided in patients with cardiogenic, traumatic, or hemorrhagic shock; cardiac dilation; and/or cerebral arteriosclerosis. Epinephrine use should be avoided in patients with organic brain damage and in patients with narrow-angle glaucoma. Administer with caution to elderly or hyperthyroid individuals, pregnant women, and individuals with cardiovascular disease or diabetes.

Adverse reactions of epinephrine include transient, moderate anxiety; feelings of over stimulation; apprehensiveness; restlessness; tremor; weakness; shakiness; dizziness; sweating; tachycardia; palpitations; pallor; nausea and vomiting; headache; and/or respiratory difficulties.

EpiPen® and EpiPen® Jr Auto-injectors are designed as emergency supportive therapy only. They are not a replacement or substitute for subsequent medical or hospital care, nor are they intended to supplant insect venom hyposensitization.
